Simulated weightbearing computed tomography for verification of radiographic staging of varus ankle osteoarthritis: a cross-sectional study

Kiyonori Tomiwa^{1*}, Yasuhito Tanaka¹, Hiroaki Kurokawa¹, Kunihiro Kadono¹, Akira Taniguchi¹ and Korakot Maliwankul²

Abstract

Background: Varus ankle osteoarthritis is classified using only weightbearing anteroposterior ankle radiographs; however, sagittal ankle alignment may also affect the position and extent of joint space obliteration. We hypothesized that the sagittal alignment of the ankle may also affect the position and extent of joint space obliteration visible on the coronal section; therefore, we identified the sites of joint space obliteration in patients with stage 3 varus ankle osteoarthritis for comparison with the sites observed on simulated weightbearing computed tomography and investigated the effects of anterior and posterior ankle subluxation.

Methods: Simulated weightbearing computed tomography scans of 83 ft with varus ankle osteoarthritis (26 stage 3a, 57 stage 3b) were performed to check for joint space obliteration in the ankle. Further classification as exhibiting either anterior, posterior, or no subluxation on weightbearing lateral radiographs was performed.

Results: Anterior, posterior, and no subluxation was seen in 5, 9, and 12 ankles among the 26 classified as stage 3a, respectively, and in 22, 12, and 23 ankles among the 57 classified as stage 3b, respectively. The mean tibial lateral surface angle on weightbearing lateral radiographs in stage 3a ankles was 75.6, 83.3, and 80.3 degrees in the anterior, posterior, and no subluxation groups, respectively; and 75.5, 86.6, and 82.7 degrees in stage 3b ankles ($p < .05$). In stage 3b ankles, widespread joint space obliteration was observed at the anterior distal articular surface of the tibia in all 22 ankles with anterior subluxation and at the posterior distal articular surface of the tibia in all 12 ankles with posterior subluxation.

Conclusions: Simulated weightbearing computed tomography revealed joint space obliteration at the anterior distal articular surface of the tibia in stage 3b ankles with anterior subluxation and at the posterior side in stage 3a and 3b ankles with posterior subluxation. In some patients with stage 3 varus ankle osteoarthritis, the obliteration of the joint space is difficult to evaluate accurately using only weightbearing anteroposterior radiographs; weightbearing lateral radiographs should also be performed.

Background

Ankle osteoarthritis is classified as either varus or valgus according to the joint alignment, with the varus type being more frequent [1]. Recent advances in operative devices and improvements in operative procedures for varus ankle osteoarthritis have led to osteotomy being commonly performed. Osteoarthritis staging is important for operative indications and selection of operative procedures. One widely used grading system for varus ankle osteoarthritis is the Takakura-Tanaka classification [2, 3], which classifies the stage from 1 to 4 based on weightbearing anteroposterior (AP) ankle radiographs. Studies of the postoperative outcomes of low tibial osteotomy have led to further subclassification of stage 3 (obliteration of the talocrural joint space) into stage 3a (obliteration of the talocrural joint space limited to the articular surface of the medial malleolus) and stage 3b (joint space obliteration also affecting the roof of the talar dome).

In general, low tibial osteotomy is indicated up to stage 3a [3]. An accurate understanding of the differences between the pathologies of stage 3a and stage 3b is important when considering the indications for osteotomy [3]. Thus far, joint space obliteration has been classified entirely on the basis of weightbearing AP ankle radiographs. However, three-dimensional (3D) studies are required to verify which parts of the articular surfaces are affected. Varus ankle osteoarthritis includes ankles in which the position of the talus is subluxated either anteriorly or posteriorly with regard to the distal articular surface of the tibia on weightbearing lateral

ankle radiographs. We hypothesized that the sagittal alignment of the ankle may also affect the position and extent of joint space obliteration visible in the coronal section.

Our objectives were to accurately identify sites of joint space obliteration in patients with stage 3a or 3b varus ankle osteoarthritis diagnosed on weightbearing AP ankle radiographs. We hypothesized that the sagittal alignment of the ankle may also affect the position and extent of joint space obliteration visible on the coronal section.

Methods

Between 2011 and 2015, 190 patients underwent surgery for varus ankle osteoarthritis at our hospital. Of these, 110 were diagnosed with stage 3a or 3b varus ankle osteoarthritis, and simulated weightbearing computed tomography (SW-CT) scans were performed on 92 ankles after obtaining written informed consent for the imaging test. The final study population comprised 26 ankles from 24 patients classified as stage 3a and 57 ankles from 53 patients classified as stage 3b, totaling 83 ankles from 77 patients.

Figure 1 shows a flowchart of the patient selection process. Staging was performed by two specialist foot and ankle surgeons using weightbearing AP ankle radiographs; if their opinions concurred, this was considered the correct stage. If they disagreed, a third foot and ankle surgeon verified their assessments, and the majority's opinion was adopted.

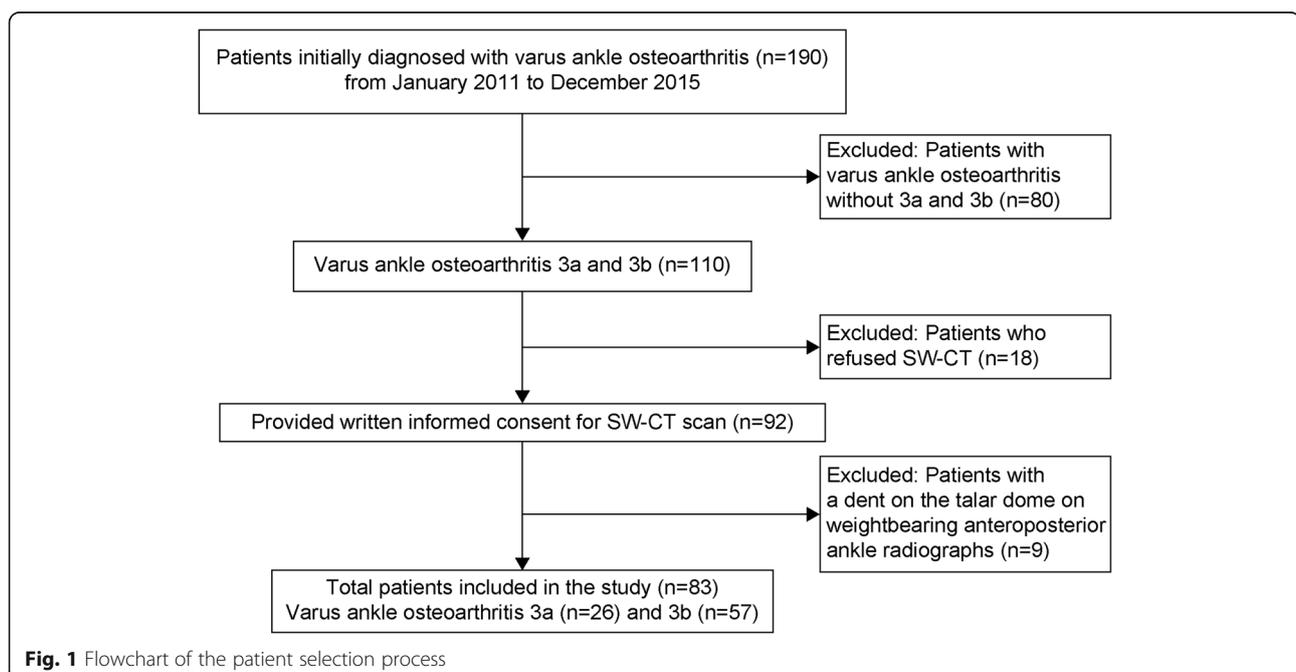

Fig. 1 Flowchart of the patient selection process

In this study, the reason to include patients classified only as stage 3a and 3b was to evaluate the pathology of pure varus osteoarthritis. This is because joint space obliteration is easy to assess, and SW-CT assessment would be more difficult at stage 1 or 2 when joint space obliteration has not occurred. Stage 4 patients were excluded because, according to Hayashi et al. [4], stage 4 encompasses different conditions, and such patients may not reflect the pathology of pure varus osteoarthritis.

Table 1 shows the demographic data of study participants. We retrospectively compared the findings of weightbearing radiographs and SW-CT scans of these feet, as described below, and investigated the extent of the effect of anterior and posterior ankle subluxations.

Radiographic method and measurements

Weightbearing AP and lateral radiographs of the ankle were performed. During this process, the patient held onto a handrail and stood on one leg while the X-ray beam was focused on the center of the ankle, and radiographs were taken from a distance of 1 m. Lateral radiographs were taken with the beam directed from the medial to the lateral side. Ankle joint alignments were measured as shown in Fig. 2.

We used the tibial lateral surface angle (\angle TLS) as a measure of sagittal alignment to investigate the effect of sagittal alignment as a cause of anterior subluxation of the talus with regard to the distal articular surface of the tibia.

Assessment and classification of talar subluxation in the sagittal plane

As there are no definite assessment criteria for ankle subluxation, we measured the positional relationship between the tibia and the talus using the same locations as used by Hackenbruch et al. [5] to measure the anterior talar translation of the ankle; this required measuring the shortest distance from the posterior margin of the

articular surface of the tibia to the articular surface of the talar dome (a) on weightbearing lateral radiographs.

We similarly measured the shortest distance from the anterior margin of the articular surface of the tibia to the articular surface of the talar dome (b). A difference between these two measurements of less than 1 mm was classified as no subluxation, while a difference of 1 mm or more was classified as subluxation. In patients with subluxation, if the distance from the posterior margin of the articular surface of the tibia to the articular surface of the talar dome (a) was 1 mm greater than the distance from the anterior margin of the articular surface of the tibia to the articular surface of the talar dome (b) ($a - b \geq 1$), this was classified as anterior subluxation. Conversely, if the distance from the anterior margin of the articular surface of the tibia to the articular surface of the talar dome (b) was 1 mm greater than the distance from the posterior margin of the articular surface of the tibia to the articular surface of the talar dome (a) ($b - a \geq 1$), this was classified as posterior subluxation (Fig. 3).

Patients were divided into subgroups according to the relative position of the talus with regard to the tibia based on weightbearing lateral ankle radiographs. Those with anterior subluxation of the talus were classified as the anterior subluxation group, those with posterior subluxation of the talus as the posterior subluxation group, and those with no obvious subluxation as the no subluxation group.

SW-CT scanning and assessment

CT scans were obtained using an OPTIMA660 device (General Electric, Boston, MA). The device used for simulated weightbearing was a DynaWell L-Spine (DynaWell Inc., Las Vegas, NV). This was used to reproduce the sagittal alignment in the standing position while the patient was supine during a lumbar CT or magnetic resonance imaging (MRI), with patients fitted with a special

border (l), and medial border (Mm) of the malleolar articular surface of the tibia (Fig. 7).

The distal articular surface of the tibia was divided into three sections anteroposteriorly (anterior, central, and posterior) and four sections mediolaterally, creating a 12-square grid (Fig. 6). Joint space obliteration was assessed in each square grid on the CT scan. For

each of the four-square grids in each (anterior, central and posterior) row, moving from the medial to the lateral side, we assessed and recorded which row had maximum damage in each case. In grids that included parts where the joint surface was not visible, assessment was only performed on the parts with visible joint surface. However, if any joint space obliteration

was seen in each grid, it was deemed that cartilage damage was observed in that particular grid. The row (anterior, central, or posterior) that contained the widest area of joint space obliteration was defined as the row with maximum damage. If two or more of the three rows had the same levels of damage, the SW-CT scans were reviewed, and the row in which the damage extended laterally for the greatest distance was considered the row with maximum damage. The malleolar articular surface of the tibia on the distal articular surface of the tibia was divided antero-posteriorly into three rows (anterior, central, and posterior) and mediolaterally into two to produce a six-square grid and was assessed in a similar manner (Fig. 7).

This study was approved by Nara Medical University Ethics Committee, Japan (IRB no. 848). Written informed consent in accordance with the Declaration of Helsinki was obtained from all study participants.

Image analysis

All radiograph and CT image data were obtained using the Digital Imaging and Communications in Medicine standard. SYNAPSE VINCENT Ver5.1 (Fujifilm, Tokyo, Japan) was used for all image measurements and analyses.

Statistical analysis

A t-test was used for all statistical comparisons between ankles classified as stage 3a and stage 3b. EZR (Easy R) on R commander (EZR Version 1.41, Y. Kanda, Saitama, Japan) was used for all statistical analyses ($p < 0.05$ was considered significant) [7].

Results

The intra-rater and inter-rater reliability was excellent for all measurements. The ICCs are presented in Table 2.

Of the 26 ankles classified as stage 3a, 5, 9, and 12 showed anterior, posterior, and no subluxation, respectively. On SW-CT, 5 out of the 9 ankles with posterior subluxation exhibited joint space obliteration at the posterior distal articular surface of the tibia, 2 of which showed widespread joint space obliteration (Fig. 8). Among the 12 ankles with no subluxation, 2 exhibited joint space obliteration at the posterior distal articular surface of the tibia.

Of the 57 ankles classified as stage 3b, 22, 12, and 23 exhibited anterior, posterior, and no subluxation, respectively. With regard to the direction of subluxation and the area of maximum damage on SW-CT, all 22 anteriorly subluxated ankles had greater damage in the anterior row (Fig. 9). Similarly, all 12 posteriorly subluxated ankles had greater damage in the posterior row. Among the 23 ankles with no subluxation, the row

∠TMM: Tibial medial malleolus angle

∠TTA: Talar tilt angle

with the maximum damage was the central row in 3 ankles. In the remaining 20 ankles, the row with the maximum damage was the anterior row in 11 ankles and the posterior row in 9 ankles (Table 3).

With regard to alignment, no significant difference was found between ankles classified as stages 3a and 3b in terms of the tibial surface angle (∠TAS) or ∠TLS, but significant differences were noted between the tibial medial malleolus angle (∠TMM) and the talar tilt angle (∠TTA) ($p < 0.05$, Table 4).

Figure 10 shows the distribution of joint space obliteration at the distal articular surface of the tibia in ankles classified as stages 3a and 3b. This figure was standardized for the distal articular surface of the tibia and the medial articular surface of the tibia of the right ankle when looking upward from the caudal side and reversed for the left foot. In most ankles, the row with maximum damage was on the same side as the direction of the talar subluxation, whether this was anterior or posterior, and its extent on the sagittal section also increased. In all cases, damage occurred in one of the rows on the medial side, and the rate of damage decreased in the more lateral rows.

In ankles classified as stage 3a, the mean ∠TLS was 75.6, 80.3, and 83.3 degrees for those with anterior subluxation, no subluxation and posterior subluxation respectively, also differing significantly among the three groups ($p < 0.05$).

In ankles with stage 3b, the mean ∠TLS was 75.5, 82.7 and 86.6 degrees in ankles with anterior subluxation, no subluxation, and posterior subluxation, respectively, differing significantly between the three groups ($p < 0.05$) (Table 5).

Discussion

In this study, we found that the site of damage to the distal articular surface of the tibia in varus ankle osteoarthritis is located either anteriorly or posteriorly according to the severity of anterior or posterior subluxation of the talus. This cannot be diagnosed by the weightbearing AP ankle radiographs conventionally used for osteoarthritis. In our study, we carried out a detailed investigation of the state of damage to the distal articular surface of the tibia and the articular surface of the medial malleolus by simulated weightbearing in the

standing position, following reports of lumbar CT and MRI scans simulating standing weightbearing [6].

In the Takakura-Tanaka classification of varus ankle osteoarthritis, the stage is classified in terms of the state of the joint space between the talus, medial malleolus, and roof of the talar dome, using weightbearing AP radiographs of the ankle [2, 3]. However, no classification has used weightbearing lateral radiographs of the ankle yet, and the site of cartilage damage in the anteroposterior orientation has not been addressed. Additionally, few studies on anteroposterior cartilage using weightbearing

lateral radiographs of the ankle have been performed. In terms of the etiology of ankle osteoarthritis, on the AP radiograph, when the distal tibial joint surface is in varus, the loading shifts to the medial side because of increased stress on that area. On the lateral radiograph, anterior loading is increased by the anterior opening of the joint [2].

In our study, we investigated anterior and posterior subluxation in stage 3 varus ankle osteoarthritis and found significant differences in the \angle TLS between ankles exhibiting anterior, posterior, and no subluxation. The anterior tilt of the \angle TLS tended to be smaller in patients with anterior subluxation of the talus and greater in those with posterior subluxation. This was found in both stage 3a and 3b ankles. When we compared the mapped sites of joint space obliteration on the distal articular surface of the tibia between stages 3a and 3b ankles and between anterior and posterior subluxation, joint space obliteration was clearly greater on the posterior side in stage 3a ankles with posterior subluxation of the talus. By contrast, in stage 3b ankles with anterior subluxation, joint space obliteration was clearly greater on the anterior side. Similarly, in cases of posterior subluxation, joint space obliteration was clearly greater on the posterior side. This was also true for ankles with posterior subluxation. We considered that when the \angle TLS is smaller and there is anterior opening of the joint, the talus is subluxated anteriorly, causing arthritis of the distal articular surface of the tibia at this site. Conversely, when the \angle TLS is greater and there is posterior opening of the joint, the talus is subluxated posteriorly, leading to arthritis mainly in this part of the distal articular surface of the tibia.

Regarding the alignment between the tibia and the talus in the lateral plane, Tochigi et al. [8, 9] reported that anterior or posterior subluxation of the talus with regard to the tibia places the joint under stress, causing ankle osteoarthritis. They also found that in 32 osteoarthritic ankles, 5 and 11 exhibited anterior and posterior subluxation, respectively, of the talus with regard to the tibial articular surface on weightbearing lateral radiographs and reported that those patients with subluxation

had end-stage ankle osteoarthritis. Veljkovic et al. [10] measured the position of the center of the talar dome in relation to the tibial axis on images from 82 patients without ankle osteoarthritis. Magerkurth et al. [11] compared 52 patients with chronic ankle instability and 52 healthy individuals and found that the position of the talar center of rotation with regard to the tibial axis was significantly anteriorized in patients with chronic ankle instability. Talar subluxation should be assessed on the basis of the relative position of the talus to the articular surface of the tibia, but currently, no study has reported the association of this direction with areas of damage to the distal articular surface of the tibia. Here, we measured the distances between the articular surface of the talar dome and the anterior and posterior margins of the articular surface of the tibia on weightbearing lateral radiographs and used them as a new index to assess the relative position of the talus in relation to the articular surface of the tibia and define subluxation.

These findings indicated the feasibility of using weightbearing lateral radiographs to verify the location of progressive cartilage damage on the distal articular surface of the tibia in patients with stage 3a or 3b varus ankle osteoarthritis. This may be helpful for preoperative planning in an attempt to distribute the load to areas with fewer arthritic changes when performing osteotomy of the distal tibia to treat varus ankle osteoarthritis, potentially improving therapeutic outcomes.

In one patient with stage 3b ankle osteoarthritis and no subluxation, the area of greatest damage was on the posterior distal articular surface of the tibia, but there was no joint space obliteration at the posterior articular surface of the medial malleolus. In another patient with no subluxation, the area of greatest damage was on the anterior distal articular surface of the tibia, but there was no joint space obliteration at the anterior articular surface of the medial malleolus. These patterns of damage are difficult to explain in terms of our present analysis, and it may be necessary to include an assessment of factors such as talar rotation.

This study has some limitations. First, weightbearing radiography was performed with the patients standing,

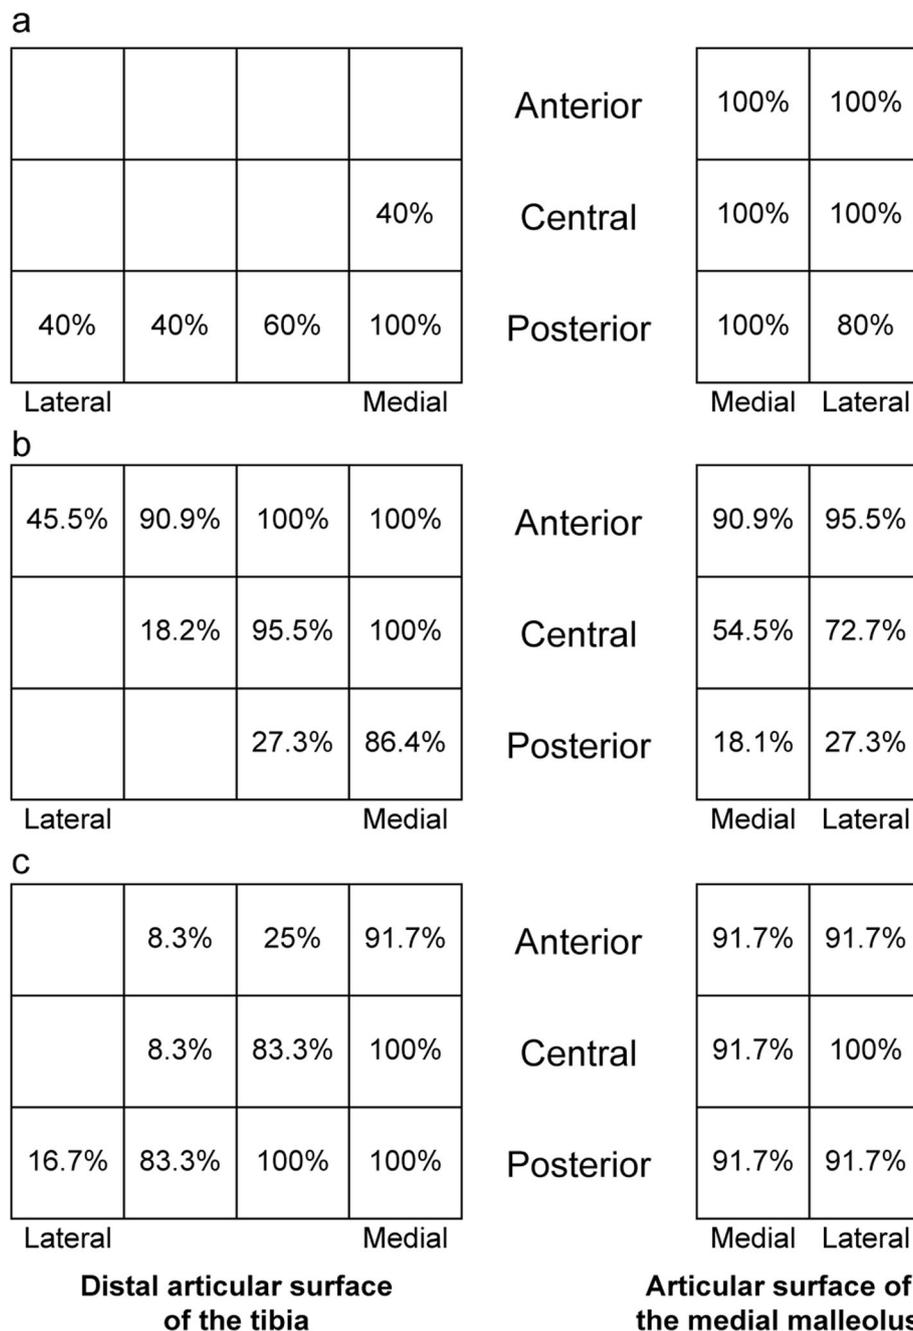

Fig. 10 Distribution of the joint space obliteration owing to talar subluxation in ankle osteoarthritis. **a** Damage rates to the distal articular surface of the tibia and articular surface of the medial malleolus in stage 3a osteoarthritis and posterior subluxation ($n = 5$). The row with maximum damage of the distal articular surface was the posterior side, defined as the talar posterior subluxation. **b** Damage rates to the distal articular surface of the tibia and articular surface of the medial malleolus in stage 3b osteoarthritis and anterior subluxation ($n = 22$). The row with maximum damage of the distal articular surface was the anterior side, defined as the talar anterior subluxation. **c** Damage rates to the distal articular surface of the tibia and articular surface of the medial malleolus in stage 3b with posterior subluxation ($n = 12$). but the SW-CT scans were carried out while they were in a supine position, which does not constitute a full weightbearing CT scan. Second, in the simulations, all patients were subjected to the same 30 kgf

weightbearing, raising the possibility that the actual extent of joint space obliteration may have been underestimated on the CT images. Third, although this study was a static analysis based on imaging, dynamic elements are

Table 5 Comparisons of the ankle \angle TLS among the three groups for stages 3a and 3b

Type	\angle TLS Mean \pm SD	Comparison	P-value

SD Standard deviation

also involved in joint space obliteration. Finally, we did not carry out quantitative assessments of other factors such as ankle instability.

In conclusion, in stage 3 varus ankle osteoarthritis, accurately evaluating not only weightbearing anteroposterior ankle radiographs but also lateral ankle radiographs before operation may help to choose the appropriate surgical intervention.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
